***Abstract*— This paper presents a low transition test pattern generator, called LT-LFSR, to reduce average and peak power of a circuit during test by reducing the transitions within random test pattern and between consecutive patterns. In other words, transitions are reduced in two dimensions, i.e. between consecutive patterns and bits. LT-LFSR is independent of circuit under test and flexible to be used for both BIST and scan-based BIST architectures. The experimental results for ISCAS'85 and '89 benchmarks, confirm up to 77% and 49% reduction in average and peak power, respectively.**

I. Introduction

Power dissipation is a challenging problem for today's system-on-chips (SoCs) design and test. In general, power dissipation of a system in test mode is more than in normal mode [1]. This is because a significant correlation exists between consecutive vectors applied during the circuit's normal mode of operation, whereas this may not be necessarily true for applied test vectors in the test mode. Low correlation between consecutive test vectors (e.g. among pseudorandom patterns) increases switching activity and eventually power dissipation in the circuit. The same happens when applying low correlated patterns to scan chains. Increasing switching activity in scan chain results in increasing power consumption in scan chain and its combinational block. This extra power (average or peak) can cause problems such as instantaneous power surge that causes circuit damage, formation of hot spots, difficulty in performance verification and reduction of the product yield and lifetime.

Built-In Self-Test (BIST) and scan-based BIST have emerged as promising solutions to the VLSI testing problems. BIST is a DFT methodology that aims at detecting faulty components in a system by incorporating the test logic on chip. BIST is well known for its numerous advantages such as improved testability, at-speed testing and reduced need for expensive external automatic test equipment (ATE). Test vectors, applied to a circuit under test at nominal operating frequency, often cause more average and/or peak power dissipation than in normal mode. The reason is that random nature of patterns, generated by an LFSR, reduces the correlation between the pseudorandom patterns and in each pattern as well. This, in turn, may result in more switchings and power dissipation in test mode.

A. Prior Work

Several techniques have been reported to address the low-power pattern generation problem. The technique proposed in [1] consists of a distributed BIST control scheme that simplifies BIST architecture for complex ICs, especially during higher levels of test activity. This approach can schedule the execution of every BIST element to keep the power dissipation under a specified limit. A BIST strategy called dual-speed LFSR is proposed in [2] to reduce the circuit's overall switching activities. This technique uses two different-speed LFSRs to control those inputs that have elevated transition densities. The low-power test pattern generator presented in [3] is based on cellular automata, reduces the test power in combinational circuits. Another low-power test pattern generator based on a modified LFSR is proposed in [4]. This scheme reduces the power in circuit under test (CUT) in general and clock tree in particular. A low-power BIST for data path architecture, built around multiplier-accumulator pairs, is proposed in [5]. The drawback is that these techniques are circuit-dependent, implying that non-detecting subsequences must be determined for each circuit test sequence. A low power BIST based on state correlation analysis proposed in [6].

Modifying the LFSR, by adding weights to tune the pseudo-random vectors for various probabilities, decreases energy consumption and increases fault coverage [7] [8]. A low-power random pattern generation technique to reduce signal activities in the scan chain is proposed in [9]. In this technique, an LFSR generates equally probable random patterns. The technique generates random but highly correlated neighboring bits in the scan chain, reducing the number of transitions and, thus, the average power. Authors in [10] proposed a method to select an LFSR's seed to reduce the lowest energy consumption using a simulated-annealing algorithm. Test vector inhibiting techniques [11] filter out some non-detecting subsequences of a pseudorandom test set generated by an LFSR. These architectures apply the minimum number of test vectors required to attain the desired fault coverage and therefore reduce power. Many low-power strategies have been proposed for full scan [13] and scan-based BIST architecture [12]. A test pattern generator for scan-based BIST was proposed in [12] that reduces the number of transitions that occur at scan inputs during scan shift operation.

B. Contribution and Paper Organization

This paper presents a new test pattern generator for low-power BIST and scan-based BIST architectures. The proposed technique increases the correlation in two dimensions, i.e. vertical dimension between test patterns (Hamming Distance) and horizontal dimension within each pattern (adjacent bits in one pattern) as well. Our technique reduces the primary inputs (PIs) activity of combinational circuits by increasing the correlation between consecutive patterns, i.e. transition between two consecutive patterns applied to CUT. It also reduces the switching activity in scan chain and its combinational clocks in a sequential circuit by reducing the transitions among adjacent bits in each pattern. Reducing the switching activity, in turn, re
reducing the power consumption, both peak and averag

introduce two low-power test pattern generation techniques and embed them into a LFSR to create our LT-LFSR. We will show that both the average and peak powers are significantly reduced using LT-LFSR.

The rest of this paper is organized as follows. Section II describes our motivation of designing a new random pattern generator. Section III decribes the randomness in test patterns generated by proposed techniques. Section IV describes implementation of the our two proposed techniques of low-power test pattern generation. The experimental results are discussed in Section V. Finally, the concluding remarks are in Section VI.

II. Motivation

Random pattern generators such as LFSR usually generate very low correlated patterns. Assume that T^i=$\{t_1^i, t_2^i, ..., t_n^i\}$ and T^{i+1}=$\{t_1^{i+1}, t_2^{i+1}, ..., t_n^{i+1}\}$, where n is the number of bits in the test patterns which is equal to either the number of PIs or length of scan chain in the circuit under test. If T^i is used for combinational circuits, then it is applied to PIs. If T^i is a pattern generated to be used in sequential circuits, it is applied to the scan-in pin (SI) of a scan chain in the circuit.

In this paper, our goal is to design a new random pattern generator that reduces the total number of transitions among the adjacent bits in each random pattern (horizontal dimension) and transitions between two consecutive random patterns (vertical dimension) as well. In other words, the new low transition random pattern generator increases the correlation between and within patterns and can be used for any circuit kind, i.e. Combinational or sequential.

• **Sequential Circuits:** Assume that pattern T^i is shifted into the scan chain and the number of transitions in each individual pattern among the adjacent bits ($\sum_{j=1}^{n} |t_j^i - t_{j+1}^i|$) is high. If low correlated patterns are used for testing sequential circuits, they will result in high number of transitions in scan chains and combinational block during shifting the patterns into the scan chains.

• **Combinational Circuits:** Assume that T^i and T^{i+1} are two consecutive patterns and the number of bit changes (transitions) between two consecutive patterns ($\sum_{j=1}^{n} |t_j^i - t_j^{i+1}|$) is high. Therefore, if low correlated patterns are applied to PIs of combinational circuits , they generate high number of transitions at the PIs which in turn results in huge number of switching activities in circuit under test.

Here, we propose a random pattern generator that combines two methods of test pattern generation called *R-Injection (RI)* and *Bipartite LFSR*. Briefly, the RI method inserts a new intermediate pattern between two consecutive test patterns by positioning a random-bit (R) in the corresponding bit of the intermediate pattern when there is a transition between corresponding bits of pattern pairs. The Bipartite LFSR generates an intermediate pattern using one half of each of the two consecutive random patterns. The main advantage of our proposed technique is that it can be used for both combinational and sequential circuits and the randomness quality of patterns does not deteriorate. There are many proposed techniques of random pattern generators that only reduce the transitions either within the patterns or between the patterns [4] [14] [9]. In other words, these techniques are just efficient to generate highly correlated patterns for either combinational circuits or sequential circuits and most of them reduces the randomness of generted patterns. This will be more elaborated in the next section.

The goal of test power reduction techniques is mostly to reduce the peak power which can cause thermal and signal integrity problems during test. However, in some cases, reducing the average test power can be beneficial as well. For example, some portable devices need to be self-tested periodically during their life time cycle [16]. Average power reduction will serve to reduce the total energy consumption, which is important for battery-powered devices and reliability.

We acknowledge that using our technique the correlation among patterns will change. However, in Section IV-D, we will show that the effect on performance to achieve a target fault coverage is negligible. Note that, even though intermediate patterns are generated between consecutive patterns, the test length (number of patterns required to achieve target fault coverage), compared to a conventional random pattern generator is quite close. This is achieved due to preserving a good quality of randomness for the inserted patterns. We will show our experimental results for both ISCAS'85 (combinational) and ISCAS'89 (sequential) benchmarks.

III. Random-Bit Injection (RI) Methodology

A. Definition of Randomness Metric

Many researchers used *entropy* as a measure of randomness metric [17]:

$$H = -\sum_{i=1}^{r} p_i \cdot log_2 p_i$$

where p_i is the probability that the signal is in state i and r denotes total number of states. This metric can quantify how the quality of pseudorandom values deteriorate if there is a biased change in bit selection or sequencing. More specifically, for an n-bit perfect random generator we have $r = 2^n$ and $p_i = 1/2^n$ and thus, the entropy will be $H = n$ reflecting the maximum randomness. For a non-ideal random generator $0 \leq H \leq n$.

B. Randomness in Conventional LFSR

LFSR units are expected to generate pseudorandom patterns that behave quite close to ideal random numbers ($H \approx n$). To show this better we analyzed the first 10000 patterns generated by a 20-bit LFSR with polynomial $f(x) = x^{20} + x + 1$. The results are shown in Figures 3, 4 and 5 for three different techniques, LFSR, Bipartite and RI, respectively.

Figure 3 shows that if number of patterns chosen ($N = 10000$ here) is large, each bit b_i would almost equally get 0s and 1s. Figures 4 and 5 pictures distribution of bit transitions vertically (between two consecutive patterns) and horizontally (among adjacent bits in one pattern), respectively. The *normal* curve behavior in Figure 4 is expected due to close-to-perfect randomness of bits generated in an LFSR.

C. Randomness in Bipartite LFSR

The implementation of a LFSR can be changed to improve some design features such as power during test. However, such modification may change the order of patterns or insert new patterns that affect the overall randomness. For exampl
pose that T^i and T^{i+1} are two consecutive patterns ge

by an n-bit LFSR. The maximum number of transitions will be n when T^i and T^{i+1} are complement of each other. One strategy used [14] to reduce number of transitions to maximum of $n/2$ is to insert a pattern T^{i1} half of which is identical to T^i and T^{i+1}. This Bipartite (half-fixed) strategy is shown symbolically in Figure 1.

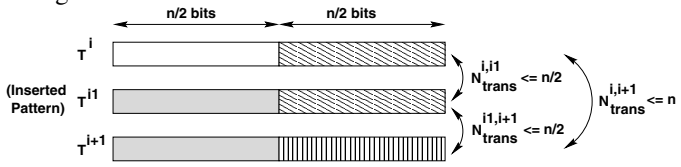

Figure 1. Pattern insertion based on Bipartite strategy.

The Bipartite strategy guarantees the transition change to be limited to $n/2$ between two consecutive patterns. However, it deteriorates the randomness to $H = n/2$. Intuitively, the worst case scenario ($H = 0$) belongs to a case in which all transitions happen in the same half that we fix. In this case, T^{i1} and T^i will be identical and adding T^{i1} has no significance for fault detection. It only prolongs the test. To see the randomness drop more clearly, we repeated the same experiment for a modified 20-bit LFSR and the results are shown in Figures 3, 4 and 5.

D. Randomness in RI-LFSR

To preserve the randomness of patterns, instead of Bipartite strategy we randomly inject a value in bit positions where $t_j^i \neq t_j^{i+1}$. Briefly,

$$t_j^{i1} = \begin{cases} t_j^i & \text{if } t_j^i = t_j^{i+1} \\ R & \text{if } t_j^i \neq t_j^{i+1} \end{cases}$$

Figure 2 shows this symbolically. The shaded cells show those bit positions where $t_j^i \neq t_j^{i+1}$. We insert a random bit (shown as R in T^{i1}) if the corresponding bits in T^i and T^{i+1} are different. Note that since such bits are uniformly distributed and also we replace them with another random value the overall randomness remains unchanged, i.e. $H = n$. Unfortunately, the maximum bit transition can be no longer guaranteed, although the expected number of transitions (mean value in the normal distribution) will be $n/2$.

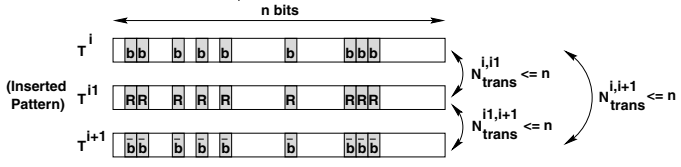

Figure 2. Pattern insertion based on random-injection (RI) strategy.

To verify the high randomness of this strategy, we repeated the same experiment for a modified 20-bit LFSR and the results are shown in Figures 3, 4 and 5.

In Section IV, we will show how to design and mix these two strategies (Bipartite and RI) to have an LFSR in which the maximum number of transitions is guaranteed to be $n/4$ while the randomness of patterns is preserved to a large extent.

IV. LT-LFSR Architecture

A. Implementing RI Technique

RI technique (Section III.D) inserts a new test pattern T^{i1} between these two test patterns such that the sum of PI's activities

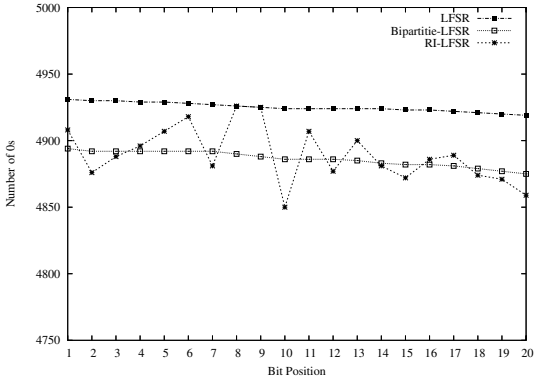

Figure 3. Distribution of 0's for three different strategy of random pattern generation, e.g. LFSR, Half-fi xed, RI and LT-LFSR.

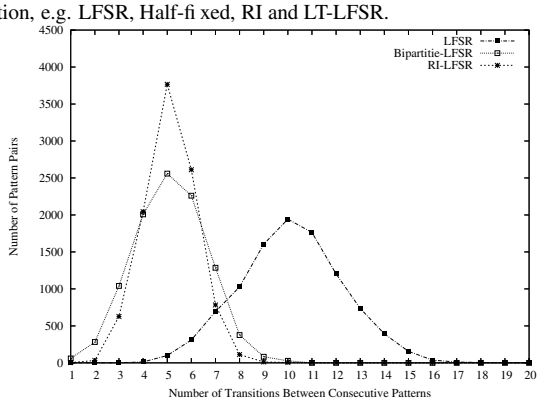

Figure 4. Distribution of number of transitions between consecutive patterns for three different strategy of random pattern generation, e.g. LFSR, Half-fi xed, RI and LT-LFSR.

between T^i and T^{it} ($N_{trans}^{i,i1}$) and T^{i1} and T^{i+1} ($N_{trans}^{i1,i+1}$) are equal to the activities between T^i and T^{i+1} ($N_{trans}^{i,i+1}$) or briefly:

$$N_{trans}^{i,i1} + N_{trans}^{i1,i+1} = N_{trans}^{i,i+1}$$

$$\sum_{j=1}^{n} |t_j^i - t_j^{i1}| + \sum_{j=1}^{n} |t_j^{i1} - t_j^{i+1}| = \sum_{j=1}^{n} |t_j^i - t_j^{i+1}|$$

Therefore, by inserting T^{i1}, $N_{trans}^{i,i+1}$ is partitioned into two parts, $N_{trans}^{i,i1}$ and $N_{trans}^{i1,i+1}$ which reduce the patterns' switching activity. When two same-position bits in T^i and T^{i+1} are equal, the same bit is placed in the same position in T^{i1}. When there is a transition between two corresponding bits in T^i and T^{i+1}, RI method injects random-bit (R).

Figure 6 shows a small example of generating intermediate pattern using RI technique. The shaded bits in T^i and T^{i+1} show

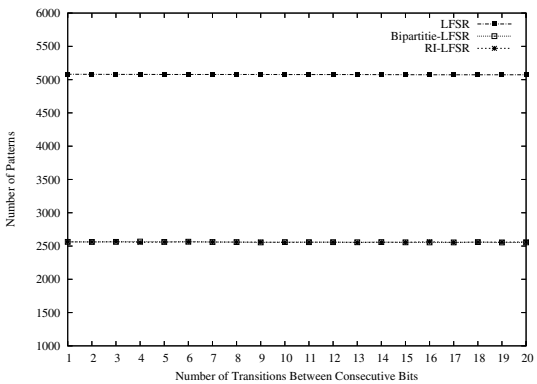

Figure 5. Distribution of number of transitions in each pattern for t ferent strategy of random pattern generation, e.g. LFSR, Half-fi xed LT-LFSR.

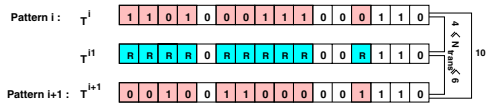

Figure 6. An example for RI.

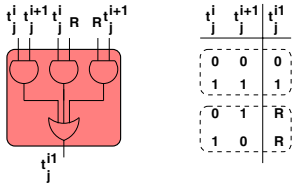

Figure 7. RI circuit.

that the number of transitions between T^i and T^{i+1} is $N^{i,i+1}_{trans}$=10 before inserting T^{i1}. For example, after generating T^{i1} using RI method, as it shows in the figure, 6 and 4 or 4 and 6 (depending R=0 or 1) transitions exist between T^i and T^{i1} and T^{i1} and T^{i+1}, respectively. There are maximum of 6 transitions for RI technique regardless of R=0 or R=1. In general, for n-bit vectors if m ($m \leq n$) transitions exist between T^i and T^{i+1}:

$$\begin{cases} Worst\ \ Case: & N^{i,i1}_{trans} = 0, N^{i1,i+1}_{trans} = m \text{ (or vice versa)} \\ Best\ \ Case: & N^{i,i1}_{trans} = N^{i1,i+1}_{trans} = m/2 \end{cases}$$

Figure 7 shows the RI unit that generates intermediate patterns. R is a random bit, which can come from one of the outputs of random pattern generator (e.g LFSR).

B. Implementing Bipartite LFSR Technique

This technique inserts an intermediate test pattern (T^{i1}) between two consecutive random patterns (T^i and T^{i+1}) such that the transitions between T^i and T^{i1} and T^{i1} and T^{i+1} are reduced. In this technique, each half of T^{i1} is filled with half of T^i and T^{i+1}:

$$T^{i1} = \{t^i_1, ..., t^i_{\frac{n}{2}}, t^{i+1}_{\frac{n}{2}+1}, ..., t^{i+1}_n\}$$

In this method an LFSR is divided into two halves by applying two complement (non-overlapping) enable signals. In other words, when one half is working, the other half is in idle mode. An LFSR including FFs with enable is shown in Figure 8(a). Figure 8(b) shows the architecture of the Bipartite LFSR to generate intermediate pattern T^{i1}. en_1 and en_2 are two non-overlapping enable signals. When en_1en_2=10, the first half of LFSR is working, while with en_1en_2=01, the second half works. The shaded flip flop is added to the Bipartite LFSR architecture to store $n/2$th bit of LFSR when en_1en_2=10 and send its value into $(n/2+1)$th flip flop when the second half becomes active (en_1en_2=01). Note carefully that the new (shaded) flip-flop does not change the characteristic function of LFSR. The LFSR's operation is effectively split into two halves and the shaded flip-flop is an interface between these two.

This method is similar to the proposed LPATPG in [14] and Modified Clock Scheme LFSR [4]. We acknowledge that although the basic idea of Bipartite LFSR is not new, but our implementation is novel and it is targeted to simplify the LT-LFSR architecture. In [14], the authors used two n-bit random pattern generator and n (2×1) multiplexers, but we only add one flip flop to an n-bit LFSR, therefore the area overhead of

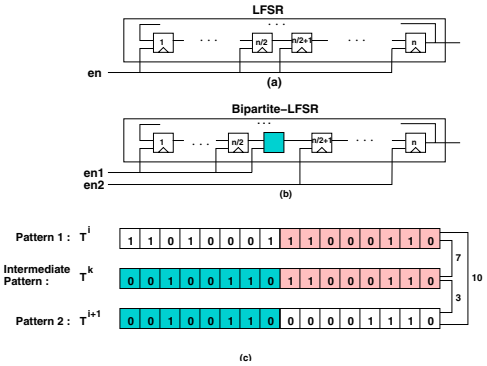

Figure 8. The Bipartite LFSR technique.

Bipartite LFSR is much lower than LPATPG. In [4] an n-bit LFSR is divided into two $n/2$-bit LFSRs which together reduce the CUT and clock tree power consumption. The drawback of this technique is that it reduces the randomness property of the LFSR due to dividing it into two smaller LFSR and also it requires generating and distributing two non-overlapping clocks (with half frequency) which in turn increases the area overhead.

Our Bipartite LFSR keeps the randomness property of the n-bit LFSR intact and it also reduces the overall power consumption of Bipartite LFSR compared to LFSR because in each period of clock half of the LFSR is in idle mode. Figure 8(c) shows a small example of inserting intermediate pattern T^{i1}, between two consecutive patterns T^i and T^{i+1}, using a 16-bit Bipartite LFSR. This reduces the bit transitions among patterns from $N^{i,i+1}_{trans}$=10 to $N^{i,i1}_{trans}$=7 and $N^{i1,i+1}_{trans}$=3.

C. Implementing LT-LFSR Architecture

We combine our two proposed techniques of pattern generation (RI and Bipartite LFSR) for low-power BIST. The new low transition LFSR (LT-LFSR) generates three intermediate patterns (T^{i1}, T^{i2} and T^{i3}) between T^i and T^{i+1}. We embed these two techniques into a bit-sliced LFSR architecture to create LT-LFSR which provides more power reduction compared to having only one of the R-Injection and Bipartite LFSR techniques in a LFSR. This may seem to prolong test session by a factor of 4. However, due to high randomness of the inserted patterns many of the intermediate patterns can do as good as patterns generated by a LFSR in terms of fault detection. In fact, in Section V we show that the overall number of LT-LFSR patterns to hit a fault coverage target obtained using LFSR is quite close to the number of conventional LFSR patterns.

Figure 9 shows LT-LFSR with RI and Bipartite LFSR included. The LFSR used in LT-LFSR is an external-XOR LFSR. As shown, injector circuit taps the present state (T^i pattern) and the next state (T^{i+1} pattern) of LFSR. Signals en_1 and en_2 select half of the LFSR to generate random patterns as shown in Figure 8. MUXs select either the injection bit or the exact bit in LFSR. One very small (46 gates. See Section V) finite state machine (FSM) controls the pattern generation process as follows:

1) **Step 1**: en_1en_2=10, sel_1sel_2=11. The first half of LFSR is active and the second half is in idle mode. Selecting sel_1sel_2=11, both halves of LFSR are sent to the outputs (O_1 to O_n). In this case, T^i is generated.
2) **Step 2**: en_1en_2=00, sel_1sel_2=10. Both halves of are in idle mode. The first half of LFSR is sent

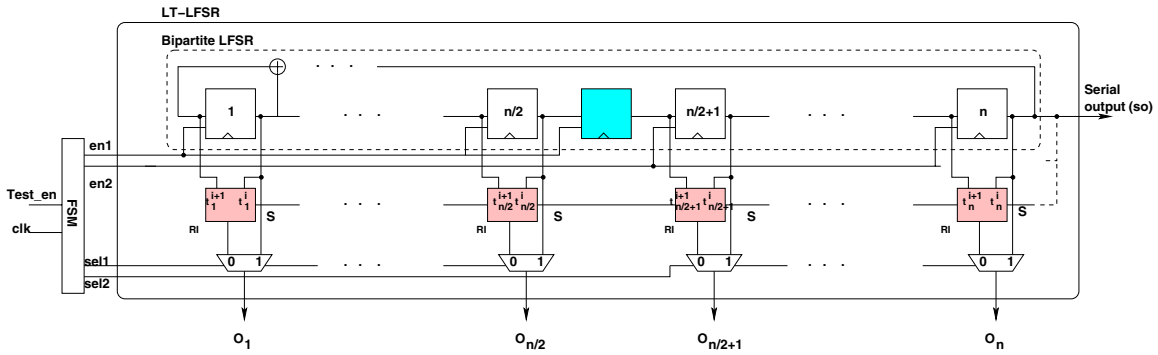

Figure 9. LT-LFSR Structure.

outputs (O_1 to $O_{n/2}$), but the RI injector circuit outputs are sent to the outputs ($O_{\frac{n}{2}+1}$ to O_n). T^{i1} is generated.

3) **Step 3**: en_1en_2=01, sel_1sel_2=11. The second half of LFSR works and the first half of LFSR is in idle mode. Both halves are transferred to the outputs (O_1 to O_n) and T^{i2} is generated.
4) **Step 4**: en_1en_2=00, sel_1sel_2=01. Both halves of LFSR are in idle mode. From the first half the injector outputs are sent to the outputs of LT-LFSR (O_1 to $O_{n/2}$) and the second half sends the exact bits in LFSR to the outputs ($O_{\frac{n}{2}+1}$ to O_n) to generate T^{i3}.
5) **Step 5**: The process continues by going through Step 1 to generate T^{i+1}.

Obviously, LT-LFSR reduces the transitions between consecutive patterns which can be used for test-per-clock architecture. The generated patterns can also be used for test-per-scan architecture to feed scan chains with lower number of transitions. We will discuss more about this in the next section.

D. Practical Aspects

• **Performance Drawback:** The additional components in LT-LFSR impose extra delay which in turn cause slight performance degradation compared to its LFSR counterpart. Our implementation using Synopsys' Design Compiler and 0.18μm indicates that in the worst case scenario, using LT-LFSR circuit, maximum of 0.1ns is added to the critical path delay of the unit due to two extra gates in RI circuit (one AND and one OR). The extra delay during test is not significant.

• **Randomness in LT-LFSR:** Figures 10, 11 and 12 show high randomness of 10000 LT-LFSR patterns generated under polynomial $x^{20}+x+1$. As seen in Figure 10, the number 0s and 1's is almost equal. Figure 11 shows that maximum $n/4$ number of transitions occur between LT-LFSR's consecutive patterns. Finally, Figure 12 shows that number of transitions in each pattern has been reduced up to four times of conventional patterns. This confirms reducing transitions during shifting patterns into the scan chains.

V. Experimental Results

In our experimentation, we used polynomial x^n+x+1 for both LFSR and LT-LFSR. The results are shown for both combinational and sequential ISCAS ('85 and '89) benchmarks. We have selected four largest ISCAS'85 and four largest ISCAS'89 benchmarks in our experiments. All circuits are synthesized using Synopsys' Design Compiler [15]. The same tool is used for scan chain insertion for ISCAS'89 benchmarks. 20 scan chains

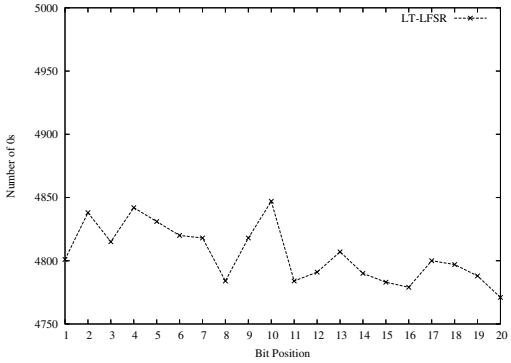

Figure 10. Distribution of 0's of random pattern generated using LT-LFSR.

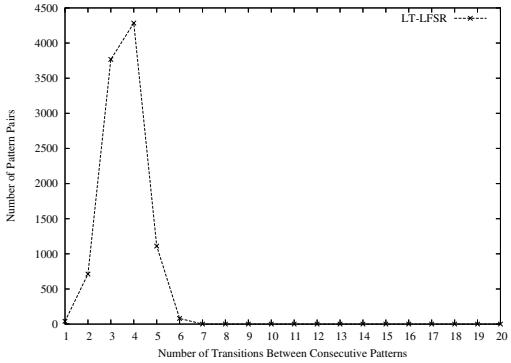

Figure 11. Distribution of number of transitions between consecutive patterns generated using LT-LFSR.

were inserted to all four ISCAS'89 benchmarks. The circuits are optimized using Artisan TSMC library based on 0.18 μm technology. Fault coverage is obtained using TetraMax tool [15] from Synopsys. Power consumption has been measured at the gate-level using PrimePower [15] assuming power supply voltage of 1.8V. The simulation is performed with back-annotation using standard delay format (SDF) file containing delay information of each gate in the netlist. This process is performed for all two test data sets, i.e. LFSR and LT-LFSR.

Table I shows the specifications of the ISCAS benchmarks and number of test patterns (N_p) required to hit a target fault coverage (FC^*) for LFSR and LT-LFSR. This table also compares our results with techniques proposed in [14] and [4] for number of patterns and fault coverage. References [14] and [4] report results only on combinational and sequential benchmarks, respectively. Reference [4] seems to limit N_p and thus achieves lower fault coverage.

In general, performance of both LFSR and LT-LFSR (N_p to hit FC^*) is seed- and polynomial-independent. Accor this table to hit the target FC^*, LT-LFSR uses +/- 10% mo

patterns that of LFSR for majority of benchmarks. As seen, in a few cases (e.g. c1908, c5315) N_p slightly (1-13%) drops showing that some of the intermediate patterns did a good job in fault detection. We used 50 different seeds for 10 different polynomials in our experiments and the results were almost the same as what are shown in the table. That confirms that the performance is seed- and polynomial-independent.

Table II shows the average and peak power of LFSR and LT-LFSR for ISCAS benchmarks. As expected, LT-LFSR significantly reduces the average and peak power. It shows that the proposed LFSR reduces the average and peak power up to 77% and 49% respectively.

VI. CONCLUSION

This paper presents a new low-power LFSR to reduce the average and peak power of combinational and sequential circuits during the test mode. The switching activity in the circuit under test and scan chains and eventually their power consumption are reduced by increasing the correlation between patterns and also withing each pattern. The experimental results indicate up to 77% and 49% reduction in average and peak power, respectively with test overhead less than 13%. This is with almost no increase in test length to hit a target fault coverage.
